Colorado Agricultural College

DIVISORS

(For the Measurement of Irrigation Water)

By

V. M. CONE, Irrigation Engineer
U. S. Office of Public Roads and Rural Engineering

The work upon which this bulletin is based was done in the hydraulic laboratory, Fort Collins, Colorado, during the seasons of 1915-16, under a cooperative agreement between the Colorado Experiment Station and the Office of Public Roads and Rural Engineering, U. S. Department of Agriculture.

DIVISORS

(For the Measurement of Irrigation Water)

By V. M. CONE, Irrigation Engineer
U. S. Office of Public Roads and Rural Engineering

Many of the canal companies of the West are co-operative stock companies in which the individual water users have rights to proportional parts of the supply of water furnished by their canal, the divisions being in the ratio of the stock owned in the canal company. Even a few rivers have their waters divided into proportional parts among the canals, regardless of the flow in the stream at any time. Under this system it is often considered unnecessary to have the water actually measured, so long as each gets his proportionate part of all the water available in the ditch or stream. This led to the use of the divisor, division box, or proportional divisor, which are different names for a device placed in a channel for the purpose of dividing the flow into two or more parts, as might be desired.

Divisors are made in many forms and sizes. In all of them the division is made in accordance with the cross-sectional area of the box, the assumption being that the rate of flow is the same in all parts of a section across the box. This assumption is incorrect to a greater or less degree, depending upon conditions as indicated in the tables contained in this bulletin, but they are convenient devices because when they have once been set, they will give approximately the same division of the flow regardless of the later increase or decrease in the main supply. However, they are inaccurate and unreliable unless constructed and operated under definite conditions and, therefore, they should not be used as measuring devices where any considerable reliability is required.

Divisors are used extensively in some districts in Colorado and Utah, but are not known in others. As early as 1867 a divisor patterned somewhat after an Italian device was used near Greeley, Colorado, by Hon. J. Max Clark.* The Max Clark box, as it is known, is used to both measure and make a fair division of the water. Its characteristic feature is an enlargement on the upstream side of the box, which reduces the velocity of the water

*Colorado Station Bulletin 27, p. 8, and U. S. G. S. Water Supply Paper 9, p. 70.

and thereby improves the value of the measurement.

Divisors are not generally applicable to use on rivers or large canals because of the difficulty in operating them. They are principally used on the smaller laterals.

The greater number of them are built to divide the flow in the ditch into two ditches, but they are made sometimes as a single structure to divide the stream into four parts or more. The divisor consists essentially of a flume or box placed in the ditch with one or more openings for side ditches and a partition board, or divisor board, which may be either fixed or movable. Movable partition boards are either hinged, as shown in Figures 1 to 6, or are made to move parallel to the side of the flume as shown in Figures 7 and 8. Provision is usually made for fastening the divisor board to a timber across the top of the box when the desired set has been made. Fixed divisor boards are used where the division of the flow is not often changed, but when a change in the division of the water between the two channels is desired, it is usually accomplished with this type of divisor by placing boards in a vertical position in one or the other of the channels. This method gives only approximate accuracy because it reduces the total available width of opening in the two channels and also changes the freedom of discharge.

When the proportional division of the flow gives a quantity too small for economical use, such as during a shortage of water late in the season, or when for any reason the supply is not sufficient to meet the demands of all the irrigators, it is better to give each user in turn a greater flow than his share, but for a proportionately shorter time. This amounts to dividing the total water available in a period of time rather than a division of the flow at a certain time.

To cover the full range of variations in sizes and methods of building boxes, and conditions of flow in the different channels would take an endless number of experiments. The tests on divisors were, therefore, confined to the forms shown in Figures 1 to 8, inclusive, and the accompanying tables are based upon the results of these 341 tests. In the table headings the word "divisor" means the channel or ditch which is taken out from the side of the main ditch; "width of divisor opening" is the distance from the upstream end of the partition board to the "divisor" side of the flume; "channel" is part of the box which carries the remainder of the flow of the main ditch; "head" is difference between the elevation of the water surface in the main ditch, taken 3 feet upstream from the end of the divisor board, and the top of the dam, or the floor of the box if no dam was used; and "effective head"

is the difference between the "head" in the main ditch and the depth of water in the "divisor" taken 3 feet downstream from the point of the divisor board.

In the experimental work the divisor board was given a bevel of 1 to 4 on the "divisor" side, leaving the end about $\frac{1}{8}$ inch thick. Rubber packing was placed under the divisor board and the board screwed to the floor of the box to insure against leakage. The flow through the "divisor" and "channel" was measured volumetrically in every experiment.

As used in the field, sometimes a drop is placed in the ditch immediately below the box, depending on which, if either, of the ditches has an excessive grade. The ditch with the drop will have the "fastest" flow, as it is commonly expressed, and, therefore, get the lion's share of the water. Since the conditions in the two ditches may be such as to produce a combination of velocities varying from slow to fast, it is evident that the divisor box cannot be classed as an accurate measuring device, and this is proved in the accompanying tables. Different types of boxes, settings of divisor board, depths of water and conditions of flow in the two ditches, are given in the tables with the hope that irrigators may know some of the facts connected with their own divisor boxes and apply the information.

A comparison of columns 2 and 3 in the tables will give the error caused by assuming the discharge to be proportional to the distances from the point of the divisor board to the sides of the flume; column 4 gives the per cent of the flow in the main ditch which will flow through the "divisor" for the corresponding width of "divisor opening" shown in column 5; and columns 6, 7 and 8 give the discharge of the "divisor", "channel", and the main ditch, respectively. To convert the discharge in second-feet, as given in columns 6, 7 and 8 into "inches" of water, multiply those values by the number of "inches" equivalent to a second-foot under the conditions in question. The quantity of water which an "inch" represents is sometimes different under neighboring canal systems.*

A dam placed across the divisor box at the point of the partition board increases the accuracy of the division of the water, its effect being most decided for low heads. When the velocity of flow was practically the same in both ditches, an effect on the division of a maximum of only approximately 1 or 2 per cent was caused by substituting a 6-inch dam for a 4-inch dam. A long box is more accurate than a short box, because the long box tends to equalize the velocities across the width of the flume be-

*See Colorado Experiment Station Bulletin No. 207.

fore the water reaches the end of the partition board. The parallel divisor board is preferable to the swing divisor board.

In addition to the tests on divisor boxes, 196 tests were made on dividing the flow over rectangular and Cipolletti weirs. Crest lengths of 2 and 4 feet were used for both types of weirs. A thin metal plate was placed on the downstream side of the weir so that its edge touched the crest of the weir and extended vertically above the weir crest into the weir notch. This plate was set for different experiments at intervals of 2 inches across the entire width of the weir, and separate channels caught the flow over the weir on the two sides of the plate. These channels were placed far enough below the crest of the weir to allow a free passage of air under the over-pouring sheet of water. Under these conditions both types of weirs give reasonably accurate divisions, the greatest error being with the rectangular weir set to divide the flow between two parties on a basis of $\frac{1}{4}$ and $\frac{3}{4}$, when the actual deliveries will be 24 and 76 per cent for a head of 0.2 foot, and 22 $\frac{1}{2}$ and 77 $\frac{1}{2}$ per cent for a head of 0.8 foot. The errors with Cipolletti weirs used as divisors were in the opposite direction and about one-half as great. When either weir would be used to divide the water equally between three parties the error would be quite negligible.

If the divisor plate is placed out some distance from the weir, or the edge is placed in a horizontal position below the weir crest, the discharge for the end division would be considerably short and the flow for the middle division would be accordingly greater than the desired amount.
